

APPARATUS AND METHOD FOR AN INTERFACE UNIT FOR DATA TRANSFER BETWEEN DATA PROCESSING UNITS IN THE ASYNCHRONOUS TRANSFER MODE AND IN THE I/O MODE

This application claims priority under 35 USC 119(e)(1) of Provisional
Application Serial Number 60/237,237, filed October 02, 2000.

RELATED APPLICATIONS

APPARATUS AND METHOD FOR AN INTERFACE UNIT FOR DATA
TRANSFER BETWEEN PROCESSING UNITS IN THE ASYNCHRONOUS
TRANSFER MODE; U.S. Patent Application No. (Attorney Docket No. TI-31779); filed
on even date herewith; invented by Shakuntala Anjanaiah and Natarajan Seshan; and
assigned to the assignee of the present application: APPARATUS AND METHOD FOR
AN INTERFACE UNIT FOR DATA TRANSFER BETWEEN A HOST PROCESSING
AND A MULTI-TARGET DIGITAL SIGNAL PROCESSING IN AN
ASYNCHRONOUS TRANSFER MODE; U.S. Patent Application No. (Attorney Docket
No. TI-33430; filed on even date herewith; invented by Martin Li, Jay Reimer Shakuntala
Anjanaiah, Natarajan Seshan and Patrick Smith; and assigned to the assignee of the
present application: and APPARATUS AND METHOD FOR INPUT CLOCK SIGNAL
DETECTION IN AN ASYNCHRONOUS TRANSFER MODE INTERFACE UNIT;
U.S. Patent Application No. (Attorney Docket No. TI-33533); filed on even date
herewith; invented by Shakuntala Anjanaiah; and assigned to the assignee of the present
application are related applications.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates generally to data processing systems and, more particularly,
to data processing systems having a host processor and at least one digital signal
processor. An interface unit is inserted between the host processor and the digital signal
processor(s) to facilitate the exchange of data there between.

2. Background of the Invention

As the requirements for computational power have increased, one data processing system that has been increasingly employed to meet these requirements includes a host processing system that controls one or more digital signal processors. The host processor is typically a microprocessor, but can be a digital signal processor. The host processor has the flexibility to respond to a wide variety of conditions and provide an appropriate response. The digital signal processors provide specialized capabilities that permit complex but repetitive tasks to be performed very rapidly. Thus, one or more digital signal processing units, operating under control of a master processing unit, can respond to a wide variety of computational intensive requirements. However, the host processor and the digital signal processor(s) may not be directly compatible and may even be fabricated by different manufacturers. In order to permit the interchange of data between incompatible components or components which can exchange data with difficulty, standard signal protocols have been agreed upon to provide the requisite commonality. As an example, the asynchronous transfer mode defines signals that facilitate the exchange of data signal groups between a host processor and a digital signal processor. A protocol has been provided for the Universal Test and Operations Phy Interface (UTOPIA) for the asynchronous transfer mode (ATM) (UTOPIA) Level 2 Interface to conform to the ATM Forum standard specification af-phy-0039.000 as well as other applicable standards. The UTOPIA protocol defines the interface between the Physical Layer (PHY) and the upper layer module such as the ATM Layer and various management entities. This definition allows a common PHY in ATM systems across a wide range of speeds and media types. The ATM cell or packet that is transferred in this protocol includes 53 bytes with a 5 byte header and a 48 byte payload in an 8-bit transfer mode, or 54 bytes with a 6 byte header and a 48 byte payload in a 16-bit transfer mode.

The UTOPIA protocol defines the exchange of data signals between master processing unit and the slave processing unit. An interface unit must be provided to buffer the data that are typically exchanged between a (relatively low-speed) communication bus and a direct memory access unit associated with the digital processing unit. In addition, to the transmit and receive functions that must be performed by the interface unit, a common configuration requires that one of the processing unit of

the system operate in a master state while one or more processing units coupled thereto have a slave status.

The asynchronous transfer mode interface unit is only one of the possible devices that can provide an interface between a digital signal processing unit and other data processing devices. Another interface device is the I/O interface unit. In fabricating a chip, the device can include one type of interface unit or both types of interface units. The inclusion of only one type of interface unit limits the utility of the chip. The inclusion of both types of interface units on a chip increases the both the size and the complexity of the chip design.

A need has therefore been felt for apparatus and an associated method having the feature that an integrated circuit chip with a digital signal processing unit can include the functionality of an I/O interface unit and a ATM interface unit. It is another feature of the present apparatus and associated method to provide an interface unit for an integrated circuit digital signal processing unit that can operate in the ATM mode or in the I/O interface unit mode. It is a more particular feature of the apparatus and associated method to provide an interface unit the can operate in the UTOPIA ATM mode or in the I/O mode.

Summary of the Invention

The aforementioned and other features can be accomplished, according to the present invention, by providing a digital signal processor configuration with an interface unit responsive to UTOPIA-defined signals. The UTOPIA interface unit is a generalized interface unit that provides UTOPIA-defined signal set to external apparatus and responds to the UTOPIA-defined signal set from an external apparatus. The interface unit exchanges signals between the direct memory access unit of the data processing unit of which the interface unit is a component and a communication bus. The signals exchanged between the interface unit and the communication buses are implemented to provide efficient transfer of data there between. In particular, the interface unit can

exchange data cells continuously with a communication bus. The interface unit includes a processor (acting as a state machine) for receiving and generating signals and buffer memory unit for buffering the flow data. The interface unit can operate in a master state with both a transmit mode and a receive mode and can operate in a slave state in both a transmit and receive mode. The interface unit can operate not only in the UTOPIA ATM interface mode but also in the I/O mode with the proper interpretation of the interface signals.

Other features and advantages of present invention will be more clearly understood upon reading of the following description and the accompanying drawings and the claims.

Description of the Preferred Embodiments

1. Detailed Description of the Figures

Referring to Fig. 1, a block diagram of the data processing system **1** capable of advantageously incorporating the present invention is shown. The data processing system includes at least one digital signal processing unit **100** through **10N**, a communication bus **110**, and a master processing unit **120**. Each digital signal processing unit **100** through **10N** includes a central processing unit (or digital signal processing unit core) **10**, memory unit **12**, a direct memory access unit **14**, and a UTOPIA interface unit **18**. The interface unit **18** of each digital signal processing unit **100** through **10N** exchanges signals with the bus **100**. Master processing unit **120** also exchanges signals with the communication bus **110**. The interface unit **18** exchanges signals with the direct memory access unit **14**. The direct memory access unit **14** exchanges signals with the memory unit **12** and, subsequently, with the core processing unit **10**. Note that the master processing unit **120** can be digital processing unit such digital signal processing unit **100**.

Referring to Table 1, the required signals for the ATM Forum Technical Committee's UTOPIA Level 2, Version 1.0 (af-phy-0039.000) are listed. Note that optional signals, not included in Table 1, are identified.

Signal Name	ATM Controller	
	Master (Dir)	Slave (Dir)
<u>Transmission Mode</u>		
UXCLK	In	In
UXADDR {4:0}	Out	In
UXCLAV	In	Out
UXENB	Out	In
UXSOC	Out	Out
UXDATA {15:0}	Out	Out
<u>Receive Mode</u>		
URCLK	In	In
URADDR {4:0}	Out	In
URCLAV	In	Out
URENB	Out	In
URSOC	In	In
URDATA {15:0}	In	In

Table 1

In the transmit slave mode, the Utopia signals have the following meaning. The UXCLK signal is a clock input signal driven by the master processing unit. The UXDATA signals and the transmit control signals are synchronized with this UXCLK signal. The UXADDR {4:0} is 5-bit address signal group generated by the master processing unit. This address signal group is used to select one of a plurality (up to 31) slave processing units in the system. The UXCLAV signal is a transmit cell available status output signal of the slave processing unit. For a cell level handshake, a 0 logic level indicates that the slave interface unit does not have a complete data cell for transmission, while a logic 1 indicates that the slave interface unit has a complete data cell to transmit. The UXENB signal is a transmit interface enable signal input signal. This signal is asserted low by the master processing unit to indicate that the slave processing unit should apply the first byte of valid data and the UXSOC (start-of-cell) signal in the next clock cycle. The UXSOC signal is the start of cell signal (active high)

that is generated by the slave processing unit on the rising edge of the UXCLK signal to indicate that the first valid byte of the cell is available on the transmit data bus. The UXDATA {15:0} signals are provided by the slave processing unit during the transmission of on the transmit data bus on the UXCLK rising edge.

5

In the receive slave mode, the URCLK signal is a clock signal applied to the interface unit by the master processing unit. The receive data and control signals are sampled and are synchronous to this clock signal. The URADDR {4:0} signals are applied to the interface unit by the master processor and identify one of the slave units (up to 31) in the system. The URCLAV signal is the receive cell available output signal from the slave interface unit to indicate that the slave interface unit has space available to receive a cell from the master processing unit. In the handshake procedure, the 0 logic bit indicates that no space is available to receive a data cell from the master processing unit. The 1 logic bit indicates that space is available to receive a data cell from the master processing unit. The URENB signal is an active low signal generated by the master processing unit to enable the receive interface of the slave processor. This signal indicates that the slave interface unit is to sample URDATA signal and the URSOC signal during the next clock cycle or thereafter. The URSOC signal is generated by the master processing unit and indicates that the first valid byte of the data cell is available on the receive data bus for the slave processor to sample. The URDATA {15:0} signals are applied by the master processor to the data receive bus and sampled on the rising edge of the CLK signal.

10

15

20

25

As can be seen from Table 1, in the master mode, the UXCLAV/URCLAV and the UXENB/URENB signals are reversed in direction when compared to the counterpart slave signals. The reversal in direction is the result of the different role played by a master mode interface unit and a slave mode interface unit. Similarly, the UXADDR and URADDR signals have reversed directions between the master mode and the slave mode resulting from the fact that the polling takes place from the master mode. The interpretation of the signals remains the same.

30

Referring to Fig. 2, the signals applied to and generated by the UTOPIA interface unit **18** in the slave transmit mode are shown. The interface unit **18** includes two components, a processor **184** acting as a state machine, and a buffer memory unit **182**. The processor **184** receives the UXCLK signal, the UXADDR {4:0} signal and the UXENB signal. The processor **184** generates the UXCLAV signal, the UXSOC signal and the UXDATA {15:0} signal. The processor **184** applies the WRD_RDY signal to the buffer memory unit and the processor **184** receives the DATA {31:0} signals and the CLAV signal from the buffer memory unit **182**. The buffer memory unit **182** receives the WD_WR signal, the ADDR {31:0} signals, the data {31:0} signals and the ADDR {31:0} signals from the direct memory access unit **14**. The buffer memory unit **182** applies the EVENT signal to the direct memory access unit **14**.

Referring to Fig. 3, a timing diagram illustrating the relationship of the signals for the asynchronous transfer mode interface unit **14** in the transmit-mode depicted in Fig. 2 are shown. The signals are synchronized by the UXCLK signal. When a slave mode asynchronous transfer mode interface unit **18** detects its address on the UXADDR {4:0} lines, the processor will provide a UXCLAV signal to indicate whether or not a cell is available for transmission. After completion of the current activity, the master processor generates the address signal group, UXADDR {4:0}, and the UXENB signal. The slave processor then transmits the data over the conductors carrying the DATA {15:0} signals and by asserting the UXSOC signal.

Referring to Fig. 4, the exchange of signals between the interface unit **18** and the master processing unit and between the interface unit **18** and the direct memory access unit **14** is shown. The processor **184** of the interface unit **18** receives the URCLK signal, the URADDR {4:0} signals, the URENB signal, the URSOC signal, and the URDATA {15:0} signals from the master processing unit. The processor **184** applies the URCLAV to the master processing unit. The processor **184** applies the DATA {31:0} signals and the WD_WR to the buffer memory unit **182** and processor **184** receives the CLAV signal from the buffer memory unit **182**. The buffer memory unit **182** applies the DATA {31:0} signals and the EVENT signal to the direct memory access unit **14** and the buffer

memory unit **182** receives the ADDR {31:0} signals and the WD_RD signal from the direct memory access unit **14**. In the slave receive mode, the DATA signals are transferred by the processor **184** to the buffer memory unit **182**, and then to the direct memory access unit **14**. The CLAV signal and the WD_WR signal permit the DATA signals to be transferred through the processor **184** to the buffer memory unit **182**. The WD_RD signal permits the DATA signals to be transferred from the buffer memory unit **182** to the direct memory access unit **14**

Referring to Fig. 5, a timing diagram illustrating the relationship of the signals for the asynchronous transfer mode interface unit **14** in the receive-mode depicted in Fig. 4 are shown. The signals are synchronized by the URCLK signal. The master processor applies the ADDR {4:0} signal group to the slave processors. The identified slave processor responds to the ADDR {4:0} signal with the appropriate CLAV signal. When an active CLAV signal is applied, the ADDR {4:0} signals are reapplied along with the ENB signal. The slave starts receiving data along with an SOC signal. The DATA {15:0} signals continue to be received until the cell has been completely transferred.

Referring to Fig. 6, the signals exchanged by the interface unit **18** in the master-transmit mode is shown. The processor **184** of the interface unit **18** receives the UXCLK signal and the UXCLAV signal. The interface unit **184** applies the UXADDR [4:0] signals, the UXENB signal, the UXSOC signal, and the UXDATA {15:0} signals to the slave processing unit. The processor **184** applies the WD_RD signal to the buffer memory unit **182** and processor **184** receives the DATA {31:0} signals and the CLAV signals from the buffer memory unit **182**. The buffer memory unit **182** applies the EVENT signal to the direct memory access unit **14** and the buffer memory unit **182** receives the DATA {31:0} signals, the ADDR {31:0} signals, and the WD_WR signal from the direct memory access unit **14**. In the master-state transmit state the DATA signals are transmitted from the direct memory access unit **14** to the buffer out memory unit **182**, and then through the processor **184** to the external component. The WD_WR signal permits the DATA signals to be transmitted from the direct memory access unit **14** to the buffer memory unit **182**. The CLAV signal and the WR_RD signal permit the

DATA signals to be transferred from the buffer memory unit **182** to the processor **184** and, subsequently to the external component.

Referring to Fig. 7, the timing diagram for the Utopia interface unit in the master-transmit state of Fig. 6 is shown. The master-transmit state processor polls, with the UXADDR {4:0} signals, the slave devices in a round robin or in a fixed priority sequence. The processor **184** receives a UXCLAV signal, where appropriate, from a slave processor following the address, UXADDR {4:0} of the processor. The master-transmit processor then reapplies the address of the slave processor generating the UXCLAV signal along with the UXENB signal. During the next clock cycle, the processor begins transmission of the UXDATA {15:0} signals and the SOC signals to the slave processor. The transfer is continued until the entire cell has been transferred.

Referring to Fig. 8, the signals exchanged by the UTOPIA interface unit **18** in the master-receive mode are shown. The processor **184** of the interface unit **18** applies the URADDR {4:0} signals and the URENB signal to the slave processing unit and the processor **184** receives the URCLK signal, the URCLAV signal, the URSOC signal and the URDATA {15:0} signals from the slave processing unit. The processor **184** applies the DATA {31:0} signals and the WD_WR signals to the buffer memory unit **182** and the processor **184** receives the CLAV signal from the buffer memory unit **182**. The buffer memory unit **182** applies the DATA {31:0} signals and the EVENT signal to the direct memory access unit **14** and the buffer memory unit **182** receives ADDR {31:0} signals and the WD_RD signal from the direct memory access unit **14**.

Referring to Fig. 9, a timing diagram is shown for the signals of the asynchronous transfer mode interface unit in the master-receive state as illustrated in Fig. 8. The master processor **184** of polls the slave processors by applying the ADDR {4:0} signals to the address line. When a slave asynchronous transfer mode interface unit is available to receive the data signals, a CLAV signal is asserted during the next clock cycle. During the following clock cycle, the ADDR {4:0} signals of the slave unit generating the CLAV signal is reapplied to the bus along with the ENB signal. When a current

interaction with the master processor is complete, the addressed slave processor transmits the DATA {31:0} signals and the SOC signal. The DATA {31:0} are transmitted until the entire cell has been transferred.

Referring to Fig. 10A and Fig. 10B, a data processing system is shown having a master-state data processing unit **91** and a plurality of slave-state data processing units **92A** through **92N**. In Fig. 10A, the master-state data processing unit **91** is in a transmit mode, while the slave-state data processing units **92A** through **92N** are in a receive mode. In Fig. 10B, the master-state data processing unit **91** is in a receive mode while the slave-state data processing units **92A** through **92N** are in a transmit mode. In Fig. 10A, the master data processing unit **91** (in the transmit mode) generates the UXCLK, the UXADDR, the UXENB, the UXSOC, and the UXDATA signals that which become the URCLK, the URADDR, the URENB, the URSOC, and the URDATA signals, respectively, when applied to the slave data processing units **92A-92N** (in the receive mode). The URCLAV signals from the slave data processing units **92A-92N** are applied to the master data processing unit **91** as the UXCLAV signal. In Fig. 10B, the master data processing unit **91** (in the receive mode) generates the URCLK, the URADDR, and the URENB signals that are applied to the slave data processing units **92A-92N** (in the transmit mode) as the UXCLK, the UXADDR, and UXENB signal respectively. The slave data processing units **92A-92N** generate the UXCLAV, the UXSOC, and the UXDATA signals that are applied to the master data processing unit **91** as the URCLAV, the URSOC, and the URDATA signals, respectively.

Referring to Fig. 11, the implementation of the UTOPIA interface unit between the communication bus **110** and the direct memory access unit **14**, according to the present invention, is shown. Data from the communication bus **110** is transferred through the interface input unit **181** to the interface input buffer memory unit **182**. From the interface input buffer memory unit **182**, the data signals are transferred through the direct memory access unit **14** to the memory unit(s) of the digital signal processing unit chip **100**. The data from the memory units is transferred through the direct memory access unit **14** to the interface output buffer memory unit **183**. The data is transferred from the

interface output buffer memory unit **183** through the interface output unit **184** to the communication bus **110**. The system logic **186** receives the INTERNAL CLOCK signal (as distinguished from the UTOPIA CLK signal), reshapes and deskews waveform and distributes the CLOCK signal to the rest of the UTOPIA interface unit **18**. The configuration interface unit **185** receives the initialization signals and, by transmission of control signals to the other units of the UTOPIA interface unit **18** determines the mode in which the UTOPIA interface unit **18** operates. These control signals are stored in the interface control register **1851**.

Referring to Fig. 12, the contents of the interface control register according to the preferred embodiment is shown. In the UREN/UXEN fields, a logic “0” indicates that the receive/transmit port is disabled, while a logic “1” indicates that the interface receive port is enabled. This designation is true in both the master and the slave modes. In the URMSTR/UXMSTR fields, a logic “0” indicates that the interface unit is operating in a slave (default) mode, while a logic “1” indicates that the interface unit is operating in a master mode. In the RUDC/XUDC fields, a user defined (i.e., standard or extended) data cell is specified for both the receive and the transmit operational modes. This field is used in the slave mode. In the SLID/SLEND field, this field identifies the address of the coupled processor unit in the slave mode. In the master mode, this field identifies the last of the processors coupled to the interface unit. In the UPM field, field identifies whether a polling takes place in a round-robin manner or from a fixed address. The U16M field determines whether data transfers are 8 bits or 16 bits for both the input and the output interfaces. The MPHY field determines whether the interface unit is coupled to a single processor (logic “0”) or to multiple processors. The ULB field determines whether the interface unit is in a loop-back mode. In the loop-back mode (i.e., logic “1”), the receive and transmit sections are coupled and the master is determined by the URMSTR/UXMSTR fields. The BEND field determines the data transfer in a big endian or little endian format.

Referring to Fig. 13, the operation of the (transmit) EVENT signal is illustrated. After initialization of the transmit portion of the UTOPIA interface unit in step 1300 or as

part of the continuing operation of the interface unit, a determination is made in step 1301 whether a space for the storage of a complete data cell is available in the transmit buffer memory unit. When the determination is yes, then in step 1302 a transmit EVENT signal is applied to the direct memory access unit. In response to the generation of the EVENT signal, a data cell is transmitted through the direct memory access unit to the transmit buffer memory storage unit in step 1303. In step 1304, as soon as the transfer of the data cell has begun and the first word of the cell is written, the EVENT signal is cleared. Note that the EVENT signal is reasserted as soon as the first word is written and the buffer memory unit has space available. The immediate reassertion of the EVENT signal improves the interface unit throughput. The process then returned to step 1301 to determine whether space in the transmit buffer memory unit is available for storage of an entire data cell. When the determination in step 1301 is negative, the process returns to step 1301 and continues to cycle until space is available for the storage of an entire data cell.

Referring to Fig. 14, the operation of the event signal in the UTOPIA slave interface unit in the receive mode is illustrated. After initialization of the receive portion of the UTOPIA interface unit in step 1400 or as part of the operation of that portion of the interface unit, a determination is made whether a complete data cell is available in the receive buffer memory unit in step 1401. When the determination is yes, a receive EVENT signal is generated in step 1402. In response to the EVENT signal, the data cell in the receive buffer memory unit is transferred through the direct memory access unit in step 1403. In step 1404, as soon as the data cell transfer is begun with the reading of the first word, the EVENT signal is cleared. The process is then returned to step 1401 and is cycled until a complete data cell is stored in the receive buffer memory unit.

Referring to Fig. 15, the connection between a Utopia protocol slave state interface unit **18** of the present invention and an exemplary digital signal processing unit I/O unit **180** is illustrated. The timing diagram for the UTOPIA interface unit signals in the I/O transmit mode is shown in Fig. 16A, while the timing diagram for the UTOPIA interface signals in the I/O receive mode is shown in Fig. 16B. The I/O signals are

typical of I/O devices, e.g., the Texas Instruments' Gigabit Transceiver. In the present invention, when the XVIO and the RVIO bits are set in the interface unit control register (cf. Fig. 12), the interface unit 18 is placed in the I/O mode and operates as an I/O device.

The relationship between the signals can be understood as follows (wherein the

5 parentheses indicate direction):

OUTDATA(out)/URDATA(in) = 8-/16-digital data input to the Utopia interface unit

OUTCLK(out)/URCLK(in) = input clock provided by the I/O device

OUTDATAVALID(out)/URENB*(in) = data valid signal from I/O device, data on bus

10 is valid only when this signal is active

OUTREADY(NA)/URENB(in) = cell available signal output from Utopia interface unit

is equivalent to a READY signal, (not used in the TLK2500, but may be useful in other devices)

INDATA(in)/UXDATA(out) = 8-/16-bit digital output from Utopia interface unit

15 INCLK(in)/UXCLK(in) = input clock provided by external source or I/O unit

INDATAVALID(in)/UXCLAV(out) = cell-available signal output from the Utopia

interface unit is used to validate data, this signal should be driven active when

UXENB* is active and valid data is on the bus.

INREADY(NA)/UXENB*(in) = data valid signal from the I/O device, data on this bus

20 is valid only when the signal is active.

The function of the CLAV signal is different in the I/O mode as compared to the Utopia mode in the Utopia interface unit 18. The operation of the CLAV signal is independent of the state of the UXENB* signal. This operational mode means that, even before the

25 port is enabled via the UXENB* signal, the data transmit queue will be available at the pins and the CLAV signal will be asserted. This feature is illustrated in the early part of Fig. 16A. The I/O device strobes the data based on the CLAV signal. During a transmit operation, if the UXENB* terminal is disabled by the I/O device, the data on the bus will be the last sent, and the next data is made available after the Utopia interface unit is

30 enabled. This feature is illustrated by element 29 in Fig. 16A. When the transmit queue is empty, the UXCLAV signal is no longer asserted after driving the last data on the bus.

The non-asserted UXCLAV signal means that the data on the bus is invalid. The UXCLAV signal will be asserted as soon as the first write to the buffer memory unit.

2. Operation of the Preferred Embodiment

5

The asynchronous transfer mode interface unit of the present invention is the interface unit between the direct memory access unit and the data processing system. In general, all of the data processing units of a data processing system can include an asynchronous interface unit using the UTOPIA protocol that is coupled to a bus coupling
 10 the data processing units. In some implementations, the data processing unit itself can be implemented to provide the asynchronous transfer mode signals thereby obviating the need for the interface unit in that data processing system. The actual transfer of the data signals between data processing systems in the asynchronous transfer mode is under the control of the same clock or synchronized clock signals. The data cells or packets that
 15 have been transferred or that are to be transferred are stored in the buffer memory unit. The memory unit provides a buffer between the clock frequency of the communication bus and the much higher frequency of the direct memory access unit.

The foregoing description has described the interface unit as including a buffer
 20 memory unit. In the preferred embodiment, the buffer memory unit is implemented by a first-in/first out memory unit. The memory unit is provided with the capacity to store two data cells. The communication bus causes the signals to be exchanged between the master unit and the slave unit to have a relatively slow clock speed. Because of the relatively slow clock speed of the communication bus, the filling or emptying of the
 25 buffer memory in the direction of the communication will be much slower than the filling and the emptying of the buffer memory unit in the direction of the direct access memory unit. Similarly, although the direct memory access unit can handle only one data transfer at a time, because of the difference in clock speed between the communication bus and the processing unit of which the direct memory access unit is a part

30

The EVENT signal is particularly useful in the efficient transfer of data cells. Because the operation of the data processing system of which the UTOPIA interface is a part is much faster than the rate at which data can be transferred over the communication bus, the transfer of data cells out of the transmit buffer memory unit and into the receive
5 buffer memory unit can be essentially continuous.

While one important application of the present invention is the transfer of data signals between a host or master-state data processing unit (that includes a microprocessor) and at least one slave-state data processing unit (that typically includes a
10 digital signal processor), this configuration can be reversed. In addition, the UTOPIA transfer mode interface unit can be added to each or a series of digital signal processing units coupled by a bus. One of the digital signal processing unit is selected as being the master-state machine and this processing unit controls the operation of all the digital signal processors.

The Utopia interface unit identifies the transfer of an incomplete ATM cell, sometimes referred to as a runt cell, when the SOC signal is set during a ATM cell transfer. In the software resolution, the runt cell can be resolved by transferring the runt cell to a higher level software procedure. In the preferred embodiment, the runt cell is
15 20 overwritten by new data under hardware control.

By proper interpretation of the signals exchanged with the communication bus, the UTOPIA ATM interface unit of the present invention can function as an I/O interface unit. This versatility permits a single interface unit to fabricated on an integrated circuit
25 chip in association with a digital signal processing unit to act in either interface capacity. The single interface unit's results in decrease in size and complexity of the integrated circuit when compared to fabricating each of the interface units in the integrated circuit.

While the invention has been described with respect to the embodiments set forth
30 above, the invention is not necessarily limited to these embodiments. Accordingly, other embodiments, variations, and improvements not described herein are not necessarily

excluded from the scope of the invention, the scope of the invention being defined by the following claims.
